Abstract

Structural control through base isolation and energy dissipation systems has been increasingly implemented worldwide in the last several years and has proven to be one of the most promising strategies for earthquake safety of structures. Nevertheless only recently there have been applications of passive structural control in Cyprus. Whereas the integration of passive damping devices within a structure aims at the energy dissipation within specific structural zones, the concept of base isolation aims at the minimization of the input seismic energy above the isolation level. The present paper gives an overview of the current application status of the control techniques to civil structures in Cyprus: A multi-storey reinforced-concrete (r/c) building of the Cyprus Sport Organization with steel diagonals and viscous dampers; a cable suspended footbridge with tuned mass dampers; three commercial buildings of steel rigid frames and braced frames, where base isolators as high damping rubber bearings, elastomeric bearings and friction pendulum bearings are placed on top of the basement columns; a building of the social activities of the University of Cyprus, partly supported on fiction seismic isolation devices; a multipurpose building for eleven rural communities with its administration cantilever unit planned to be interconnected with friction pendulum bearings; a retrofit planned for a multi-storey building for the Telecommunications Authority of Cyprus, partly to be supported on friction seismic isolation devices; and four highway bridges, supported on either elastomeric bearings with dual lead cores or on friction pendulum bearings.

Keywords: structural control, energy dissipation, seismic isolation, seismic performance.
1 Introduction

Cyprus has a long historical record of damaging earthquakes and life loss. Compared to many areas of the world, the pre-1900 earthquake history of Cyprus is relatively well known back to at least 92 BC [1], although the first seismograph was installed in 1984 and the seismograph network was upgraded in two subsequent phases 13 and 8 years ago, respectively. Most of what is known about the seismicity of Cyprus since the 20th Century is found in the records of regional seismic networks in the central and eastern Mediterranean area and from international earthquake centers.

The national earthquake resistance regulations comply with Eurocode 8, based on the capacity design of the structures according to the ductility classification of the systems. Major improvement in the national annex of the code is the redefinition of the seismic zones in Cyprus with substantial increase of the design acceleration for elastic response.

In improving further the earthquake resistance of the structures within acceptable ranges, passive control may be achieved with the integration of damping devices into the structure or the isolation of the building from the ground excitations. In the first case, the energy dissipation process is controlled within the structure. In the second case, the input earthquake energy of the structure is itself minimized, by avoiding resonance and the earthquake induced forces are transmitted from the low tuned bearings to the building as significantly smaller shear forces, through oscillations at lower frequency. The deformations are confined to the isolation level. The current status of application of passive structural control techniques in building and bridge design in Cyprus is presented.

2 Seismicity

2.1 Regional tectonics

Cyprus lies on the southern part of the diffuse boundary between the African and Eurasian plates in a general zone of shortening, which extends between the Gulf of Antalia in the west and the Gulf of Iskenderun in the east. In the west the Cyprean Arc meets the eastern end of the Hellenic Arc under southern Turkey in an area with subcrustal and intermediate depth earthquakes. In the east, it joins the east Anatolian fault zone, which extends northeastwards through Turkey from the continuation of the Dead Sea rift system up the Syrian coast [2]. Hence, Cyprus lies near the junctures of several tectonic elements.

In the past, Cyprus was affected by many earthquakes, although the level of earthquake activity in Cyprus can be considered to be less than that of high seismicity regions of Greece and Turkey. During the last Century, Cyprus has been affected by approximately 28 earthquakes with magnitude greater than 4.7 on the Richter scale. This gives approximately a return period of 120 years for a destructive earthquake with maximum intensity VIII on the Modified Mercalli scale [3].
As regards the earthquake activity distribution, this is predominant in the southeast direction of the island. To the northwest of the island there is an area of lower activity with quiescence for over 100 years and the active area in the Gulf of Antalia. In general, earthquake focal depths in the Cyprus region range from very shallow depths to over 100 km. Regarding the chronological level of activity, there is a higher level during the early decades of the 20th Century. In addition, the activity is not uniform with time; half of the events registered occurred in the 20-year period 1918-1937 and the last decades since 1960 contain only 6 events. For the northwest part of the region, in the Gulf of Antalia, all 16 events found, occurred after 1924, while the activity was highest in the 1920s and 1930s.

2.2 National Earthquake Regulation as to EC 8

The Type 1 elastic response spectrum, as adopted in the Cyprus National Annex CYS EN 1998-1:2005, of Eurocode 8: Design of Structures for Earthquake Resistance [4], is specified for ground types A to E to represent the horizontal components of the seismic action. The definition of the reference peak ground acceleration on Type A ground, $\alpha_{gR}$, is according to the seismic zonation map of Cyprus as shown in fig. 1, accounting to a value of 0.25g.

3 Structural control techniques

3.1 Applications

Only recently there have been specific proposals or practical implementations of structural control techniques in Cyprus, including the following projects:
- A multi-storey r/c building of the Cyprus Sport Organization with steel diagonals and viscous dampers.
- A cable suspended footbridge above the highway with tuned mass dampers at the supports.

Figure 1: Recommended Type 1 elastic response spectrum for ground types A to E for 5% damping, CYS EN 1998-1:2005 and Seismic Zonation Map of Cyprus, CYS EN 1998-1:2005.
- A commercial building center, where base isolators as high damping rubber bearings are placed on top of the basement columns.
- A commercial building, with elastomeric bearings and friction pendulum bearings.
- A building of the University of Cyprus, partly supported above ground on friction isolation devices.
- A multipurpose communities building with an administration cantilever unit interconnected with friction pendulum bearings.
- A proposal for the retrofit for a multi-storey building for the Telecommunications Authority of Cyprus, partly to be supported on friction seismic isolation devices.
- Highway bridges, supported on elastomeric bearings with dual lead cores.
- Highway bridges, supported on friction pendulum bearings.

3.1.1 Energy dissipation systems
The administration building of the Cyprus Athletic Organization is a 3-storey building with an almost rectangular shape. The building consists of two externally positioned parts in the longitudinal direction, interconnected in the middle zone through a central core (fig. 2). The ground floor area is almost open. The structure of the building consists of r/c frames and the shear walls of the core. The frames at the ground floor are equipped with scissor-jack-dampers for earthquake resistance [5].

The applied system magnifies, through its configuration, the damper displacement for a given inter-storey drift and the damper force output delivered to the structural frame. The system thus extends the applicability of damping devices to cases of small inter-storey deflections, such as stiff structures under seismic loading. In addition, the scissor-jack damping system allows for open spaces at the ground level through its compactness and near-vertical installation.
The footbridge at the highway knot of Saint Athanasios, north of Limassol, has a width of 8.5 m and spans 48 m free (fig. 3). Two longitudinal, primary girders are suspended through eight cables from two inclined masts at the sides, of 10 m height. The primary girders are supported at the ends on tuned mass dampers for the reduction of the relative displacements of the structure under live loads. The steel structure has been designed to withstand elastically a maximum ground acceleration of 0.25g.

3.1.2 Base isolation
A commercial building center with two building sections (IKEA premises and the Cyprus Mall) with an area of 40,000 m², is supported on high damping rubber bearings (HDRB) (fig. 4). The elastomeric bearings have vertical load capacities ranging from 2.9 to 9.1 MN. The maximum relative horizontal displacement of the bearings is 80 mm, while their effective stiffness varies from 2.5 to 3.5 MN/m. The designers provided a seismic buffer in case the provided clearance around the building is exceeded in an earthquake event.

Another commercial two-storey building in the area has been constructed in steel (fig. 5). The storey structure above ground level consists mainly of storey frames that are additionally braced. Longitudinally, the primary beams are partly suspended from the columns, from the upper storey. The relatively flexible upper structure is supported on the r/c underground storey over elastomeric bearings with seismic buffers and friction pendulum bearings.

The recently constructed building of social activities of the University of Cyprus develops on the three periphery sides of the plot allowing for major interaction in its usages with the outer open spaces. The east first storey wing of the building consists of a steel frame structure supported on seven V-shaped r/c columns and friction isolation devices (fig. 6). The friction pendulum bearings have an outer diameter of 500 mm and a height of 150 mm. The maximum displacement of the bearings accounts to 125 mm and their respective maximum horizontal loading, 1200 kN.

Figure 5: Commercial building with elastomeric bearings and friction pendulum bearings.
Figure 6: University of Cyprus building of social activities partly supported above ground on friction pendulum bearings.

The design of a multipurpose building of about 2,000 m$^2$ for eleven rural communities, planned for construction on a mountainous landscape north of Limassol, consists of an autonomous unit of administration, transversely elevated above the main building (fig. 7). The administration building unit forms a cantilever with a length of 10 m. The building unit consists of a horizontal storey-high Vierendeel-tube, supported on one side by the core and two pairs of composite columns. The last three vertical frames of each Vierendeel are additionally braced behind the façade planes. For avoiding excessive torsional effects of the building unit under earthquake loads, all vertical supports are to be cut off and interconnected with friction pendulum bearings above the entrance level. The friction bearings with an outer diameter of 500 mm and a height of 150 mm, were selected for their low vertical dimensions and after having confirmed that no up-strain forces develop at the supports of the building unit.

The central administration building of the Cyprus Telecommunications Authority was designed in 1978 according to the national earthquake resistance code provisions of that time. A design acceleration of 0.04g for elastic response was taken into account. The 5-storey building with hexagonal form has a non-
uniform stiffness distribution. The structure of each rectangular part forming a side of the hexagon consists of r/c frames with shear walls at the end of each side, as shown in fig. 8. The period of the fixed supported building is 0.49 s.

Figure 8: Central administration building of the Cyprus Telecommunications Authority.

A proposed retrofit of the building refers to an acceleration value of 0.25g [6]. Through introduction of seismic isolation – friction pendulum bearings – at the ground level, the structure will develop exclusively translational modes without any substantial torsional effects. The periods of the isolated system in the two main directions are calculated at 1.60 s and 1.57 s. The increase of the period of the isolated system will lead to a substantial decrease of the seismic design forces, corresponding to a design acceleration of 0.09g for the elastic response. In addition, thanks to the base isolation, the requirement for supplementary reinforcement of the columns is kept to a minimum; the foundation does not require any strengthening and the inter-storey deflections become minima, enabling the building to behave as a rigid body.

Highway bridges, which have been recently constructed as junction overpasses on the outskirts of Limassol, are supported on elastomeric bearings with dual lead cores (fig. 9). The bearings have rectangular shapes with dimensions ranging from 600×600 to 900×850 mm. Their maximum vertical load capacity varies from 5.5 to 12.1 MN, while their maximum horizontal relative displacements range from 185 to 270 mm.

Figure 9: Bridge sector with elastomeric bearings with dual lead cores.
Similar elastomeric bearings with dual lead cores have been implemented in another highway bridge sector, Mesa Geitonia, north-east of Limassol, as shown in fig. 10.

Friction Pendulum Bearings have been installed at another overpass highway bridge in Limassol and the Amathos river bridges (fig. 11). The pier bearings installed, have a displacement capacity of 280 mm and an effective stiffness of 5.34 MN/m. The abutment bearings have a displacement capacity of 318 mm and an effective stiffness of 1.7 MN/m.

4 Conclusions

An overview of the current situation regarding code provision and application in earthquake resistance issues in Cyprus proves that an immense improvement in the design, implementation and development of modern control techniques may be observed over the past years. The new national regulations on the basis of Eurocode 8 will increase the awareness in practice towards a performance-based design for structural safety. Based on the presented overview of applications of energy dissipation systems and seismic isolators in Cyprus, it is expected that applications of passive control techniques in both new and existing buildings will exponentially increase in the next years.
